Abstract Pepper (*Capsicum* L.) is a nutritionally and economically important crop that is cultivated throughout the world as a vegetable, condiment, and food additive. Genetic transformation using *Agrobacterium tumefaciens* (agrobacterium) is a powerful biotechnology tool that could be used in pepper to develop community-based functional genomics resources and to introduce important agronomic traits. However, pepper is considered to be highly recalcitrant for agrobacterium-mediated transformation, and current transformation protocols are either inefficient, cumbersome or highly genotype dependent. The main bottleneck in pepper transformation is the inability to generate cells that are competent for both regeneration and transformation. Here, we report that ectopic expression of the *Brassica napus* BABY BOOM AP2/ERF transcription factor overcomes this bottleneck and can be used to efficiently regenerate transgenic plants from otherwise recalcitrant sweet pepper (*C. annuum*) varieties. Transient activation of BABY BOOM in the progeny plants induced prolific cell regeneration and was used to produce a large number of somatic embryos that

could be converted readily to seedlings. The data highlight the utility of combining biotechnology and classical plant tissue culture approaches to develop an efficient transformation and regeneration system for a highly recalcitrant vegetable crop.

Keywords Sweet pepper (*Capsicum annuum*) · Transformation · *Agrobacterium* · BABY BOOM · Somatic embryogenesis · Regeneration

Abbreviations

TDZ	Thidiazuron

Introduction

The genus *Solanaceae* comprises some of the most economically important vegetable species, including potato (*Solanum tuberosum*), tomato (*Solanum lycopersicon*), eggplant (*Solanum melongena*), and pepper (*Capsicum* spp.). More than 40 species belong to the genus *Capsicum*. Five pepper species, *C. annuum*, *C. frutescens*, *C. baccatum*, *C. chinense*, and *C. pubescens*, are valuable crops plants that

are cultivated and consumed throughout the world, with *C. annuum* being the most widely cultivated species. Pepper is second only to tomato in terms of vegetable production in developed countries, and its breeding and production, as with other major crops, is constantly challenged by numerous pests, diseases, and abiotic stresses (Djian-Caporalino et al. 2007). Trait development in the genus *Capsicum* is hampered by interspecific crossing barriers, as well as by the general lack of an efficient regeneration system, which is a prerequisite for the introduction of new traits by genetic transformation. The major bottlenecks in *Capsicum* regeneration are the general low frequency of shoot formation and the development of malformed shoot buds and shoots (variously referred to in the literature as rosette shoots, leafy shoots or blind leaves) that fail to elongate, most likely due to the absence of a shoot apical meristem (Dabauza and Pena 2003; Engler et al. 1993; Kothari et al. 2010; Liu et al. 1990; Mihálka et al. 2003; Wolf et al. 2001). In general, the chili (hot) pepper types are much more responsive for in vitro regeneration than the sweet pepper types (Dabauza and Pena 2001; Engler et al. 1993; Khan et al. 2006; Lopez-Puc et al. 2006; Ochoa-Alejo and Ramirez-Malagon 2001; Solís-Ramos et al. 2010; Zapata-Castillo et al. 2007) although a strong genotype dependency has been observed in both.

Agrobacterium tumefaciens (agrobacterium)-mediated transformation of *C. annuum* has been described in the literature, but in most reports only a few transgenic lines were obtained, and/or the transformation efficiency and heritability of the transgene were not reported (Dabauza and Pena 2003; Manoharan et al. 1998; Mihálka et al. 2003; Shivegowda et al. 2002; Zhu et al. 1996). Reproducible agrobacterium-mediated transformation is currently limited to a few responsive chili pepper genotypes (Ko et al. 2007; Lee et al. 2004) and one sweet-mini pepper genotype (Engler et al. 1993; Harpster et al. 2002). The difficulties associated with pepper transformation have been attributed to its low regeneration capacity, and the poor overlap between the tissues that are competent for agrobacterium infection and those that are competent for regeneration (Wolf et al. 2001). This is a general phenomenon that has been observed in plants that are recalcitrant for transformation (Potrykus 1991). A system that supports transformation and regeneration of the same tissues could therefore provide the basis for an efficient pepper transformation protocol.

A number of genes encoding transcription factors, cell cycle proteins, and components of hormone biosynthesis and signaling pathways have been shown to enhance plant regeneration responses when mutated or ectopically expressed (Banno et al. 2001; Catterou et al. 2002; Lotan et al. 1998; Riou-Khamlichi et al. 1999; Zuo et al. 2002). One of these genes, *BABY BOOM* (*BBM*), encodes an AP2/ERF transcription factor that induces regeneration under

culture conditions that normally do not support regeneration in wild-type plants. Ectopic expression of *Brassica napus BBM* (*BnBBM*) genes in *B. napus* and the related crucifer arabidopsis (*Arabidopsis thaliana*) induces spontaneous somatic embryogenesis and organogenesis from seedlings grown on hormone-free basal medium (Boutillier et al. 2002). In tobacco, ectopic *BBM* expression is sufficient to induce adventitious shoot and root regeneration on basal medium, but exogenous cytokinin is required for somatic embryo (SE) formation (Srinivasan et al. 2007). Ectopic *BBM* expression has also been used to generate transgenic Chinese white poplar (*Populus tomentosa* Carr.) plants (Deng et al. 2009). Poplar callus transformed with a *B. rapa BBM* gene developed SEs that could be converted into plantlets, while untransformed callus failed to regenerate. The system was combined with heat shock-inducible FRT/FLP-mediated excision of the transgene to produce marker-free lines.

Transformation strategies based on standard tissue culture approaches have not led to efficient pepper transformation protocols. We therefore examined whether the positive influence of *BBM* expression on regeneration that is observed in other plant species could be transferred to pepper. Here, we describe the efficient regeneration of large numbers of fertile transgenic plants of two *C. annuum* sweet pepper varieties by combining a classical tissue culture approach with transient activation of a *BnBBM* protein.

Materials and methods

Explant pre-culture

Surface sterilized seeds of the F1 hybrids Fiesta, Ferrari, and Spirit (Enza Zaden, The Netherlands) were sown on full strength MS medium (Murashige and Skoog 1962) with 2% (w/v) sucrose (pH 5.8, MS20) solidified with 0.8% (w/v) Microagar. Ten-day-old petiole-free cotyledons were cut twice, transverse to the mid-rib, to generate three explants, which were then pre-cultured on solid (0.7% Microagar) co-cultivation medium (CCM) supplemented with 40 mg/l acetosyringone (Acros Organics) for 1–2 days under dim light conditions (1,500 lux) at 23°C. CCM is a modified R medium (Sibi et al. 1979) supplemented with 1.6% (w/v) glucose, 2 mg/l zeatin riboside and 0.1 mg/l indole-3-acetic acid to promote shoot regeneration.

Agrobacterium and vectors

Agrobacterium strain GV3101 carrying the pMP90 Ti plasmid was used in all experiments. Agrobacterium containing the *35S::BnBBM:GR* (Srinivasan et al. 2007) and

35S::*GUS* binary vectors were grown with the appropriate antibiotics in 100 ml YEB medium at 28°C. Prior to transformation the agrobacterium suspension was diluted to OD₆₆₀ 0.3–0.4 with liquid CCM supplemented with freshly prepared 40 mg/l acetosyringone.

Transformation and regeneration

The diluted agrobacterium culture was added to the pre-cultured cotyledon explants and incubated at room temperature for 30–60 min. Explants were blotted dry and further co-cultured on CCM supplemented with 40 mg/l acetosyringone for 2–3 days under dim light conditions (1,500 lux) at 23°C before transfer to selection medium consisting of CCM supplemented with 1 mg/l thidiazuron (TDZ), 100 mg/l kanamycin sulfate and 500 mg/l cefotaxime. Explants were transferred to full light conditions (3,000 lux) on a 16 h/8 h day/night cycle at 23°C for 2 months. The medium was refreshed after 4 weeks. Explants with emerging shoots or shoot-like structures (SLS) were transferred for 4 weeks to elongation medium (EM) consisting of MS macro- and microsalts (Murashige and Skoog 1962), B5 vitamins (Gamborg et al. 1968), 1.6% (w/v) glucose, 1 mg/l inositol, 20 mg/l adenine sulfate, 200 mg/l casein hydrolysate, 10 mg/l gibberellic acid 3, 4 mg/l benzylaminopurine and 30 µM silverthiosulfate. Elongated shoots were transferred to pre-rooting medium (PRM), comprising MS20 medium supplemented with 30 mg/l glutathione, 60 mg/l kanamycin sulfate, and 300 mg/l cefotaxime. The shoots were transferred after 1 month to rooting medium (RM; Rugini 1984) supplemented with 2% (w/v) sucrose, 50 mg/l kanamycin. Rooted shoots were transferred into the greenhouse for seed set. All media used in experiments involving the 35S::*BnBBM:GR* construct were supplemented with 10 µM dexamethasone (DEX; Sigma) up to the point where shoots were transferred to EM, after which DEX-free media was used. Except where noted, all tissue culture chemicals were supplied by Duchefa Biochemicals (Haarlem, The Netherlands).

β-Glucuronidase (GUS) staining

Histochemical GUS staining (Jefferson 1987) of 35S::*GUS* explants was performed after 3 weeks on selection medium.

Evaluation of stable transgenic lines of 35S::*BnBBM:GR*

Surface sterilized seeds were sown on MS20 medium supplemented with either 10 µM DEX, 1 mg/l TDZ, or

10 µM DEX plus 1 mg/l TDZ. The response of the seedlings was evaluated 24 days after sowing.

Root, hypocotyl, and cotyledon explants from 10-day-old seedlings and leaf explants from 4-week-old plantlets were obtained from donor material grown on MS20 without any supplements. Explants were placed on MS20 or MS20 supplemented with 10 µM DEX, either alone or in combination with 1 mg/l TDZ, benzylaminopurine or zeatin riboside. The response of the explants was evaluated after 2 weeks. Conversion of SEs into plantlets was assessed by placing embryos onto RM. Conversion into plantlets was evaluated 4 weeks after transfer to RM.

Results

BABY BOOM-mediated regeneration

We examined the utility of a *BnBBM* gene as a tool to enhance regeneration during agrobacterium-mediated transformation of *C. annuum* sweet, blocky pepper types. Ectopic BBM expression induces pleiotropic phenotypes such as adventitious growth and sterility that are likely to interfere with the regeneration process and subsequent growth of transgenic plants (Boutillier et al. 2002). To avoid generating plants with detrimental phenotypes, we expressed a fusion between the BnBBM protein and the ligand binding domain of the rat glucocorticoid receptor (BBM:GR), which sequesters the BBM transcription factor in the cytoplasm in the absence of glucocorticoid steroid, e.g., DEX (Passarinho et al. 2008; Srinivasan et al. 2007). Explants were co-cultivated with agrobacterium carrying either the 35S::*BnBBM:GR* construct or a control 35S::*GUS* construct carrying the scorable GUS marker. Both constructs confer kanamycin resistance via the *nptII* selection marker. Explants were co-cultivated with agrobacterium on CCM and then transferred to CCM medium containing kanamycin until shoots appeared, at which point the shoots were transferred to EM. Elongated shoots were then transferred to PRM and subsequently to RM when rooting did not occur already on PRM. Approximately 5,600 explants from two cultivars were used in the transformation experiments with the 35S::*GUS* plasmid, and approximately 6,400 explants from three cultivars in the transformation experiments with the 35S::*BnBBM:GR* plasmid (Table 1).

Cotyledon explants that were co-cultivated with agrobacterium containing the 35S::*GUS* construct behaved as previously described for poorly regenerating or non-transformable genotypes (Lee et al. 2004; Liu et al. 1990). The explants increased in size about twofold during the first 3 weeks on selection medium. Small calli became

visible at the cut edge of the explants during the following 2–4 weeks, accompanied by a few dense rosette-forming SLS (Fig. 1a, b). SLS transferred to EM failed to elongate and therefore did not root when transferred to rooting medium (RM). In vitro grafting of the SLS onto a wild-type rootstock did not promote further shoot development or elongation, suggesting that the SLS lacked a functional apical meristem. In a separate experiment, histochemical staining of 3-week-old explants ($n = 225$) that formed both SLS and callus showed that 6% of the

explants exhibited GUS activity and that the GUS activity was restricted to the developing callus (Fig. 1c). This observation supports the hypothesis of Wolf et al. (2001) that under these conditions, pepper cells that are susceptible for agrobacterium transfection lack regeneration capacity and vice versa.

In contrast to the control experiments with the *35S::GUS* construct, co-cultivation of sweet pepper cotyledon explants with agrobacterium carrying the *35S::BnBBM:GR* construct allowed us to generate numerous transgenic

Fig. 1 Regeneration response of sweet pepper explants. Rooting of elongated shoots	14	RM
Total	150	

CCM co-cultivation medium, MS20 Murashige and Skoog (1962) with 2% (w/v) sucrose, ZR zeatin riboside, IAA indole-3-acetic acid, ACS acetosyringone, TDZ thidiazuron, DEX dexamethasone, EM elongation medium, PRM pre-rooting medium, RM rooting medium

shoots that stably transmitted the transgene to the next generation. The transformation experiments with the *35S::BnBBM:GR* plasmid were carried out as described above, except that 10 μ M DEX was included in the selection medium to localize the BBM:GR protein to the nucleus. Explants co-cultivated with the *35S::BnBBM:GR* agrobacterium behaved essentially the same as in the *35S::GUS* experiments during the first 7 weeks of culture, except that they produced more SLS in each experiment compared to the *35S::GUS* control (Table 1). Unlike the control experiments with *35S::GUS*, the SLS that formed after co-cultivation with the *35S::BBM:GR* agrobacterium elongated and proliferated within 4 weeks after transfer to EM (Fig. 1d). SEs developed occasionally on the leaves of elongated shoots and/or SLS that remained in contact with the medium (Fig. 1e), and in turn produced elongated shoots. Plantlet formation from elongated shoots was enhanced after transfer to PRM (Fig. 1f). Shoots that did not root on PRM formed roots within 2 weeks after transfer to RM. An overview of the workflow for our sweet pepper transformation protocol is shown in Table 2.

In total, 98 rooted shoots regenerated from 35 independent SLS were transferred to the greenhouse. PCR on T0 plants and germination of T1 seed on kanamycin-containing medium suggested that all 98 plants were transgenic (data not shown and Supplementary Table 1). A more detailed PCR analysis of 65 T1 lines derived from 31 SLS (Supplementary Fig. 1) showed that the *35S::BBM* fragment (located close to the right T-DNA border) could be amplified in all 65 lines, while the *nos::nptII* fragment (located close to the left border) could only be amplified in 62/65 lines (Supplementary Fig. 1). The three lines lacking the *nos::nptII* fragment showed kanamycin resistance,

suggesting that the selection marker was truncated during T-DNA integration but is still functional.

Regeneration and transformation efficiency

The regeneration response of the three tested varieties was greatly enhanced in the experiments with the *35S::BnBBM:GR* plasmid (Table 1) although genotypic differences were observed among the varieties with respect to the different steps in the regeneration protocol. In all cases, co-cultivation with the *35S::BnBBM:GR* plasmid was able to relieve one or more bottlenecks in the regeneration/transformation procedure for each of the varieties tested. Transgenic plantlets were generated for two of the three varieties, whereas no transgenics were obtained from any variety in the control experiments. Numerous elongated shoots could be produced from a single SLS. However, as multiple shoots may arise from a single transformation event, we only used a single elongated shoot per SLS to calculate the transformation efficiency (Table 1). Based on this criterion, we obtained average transformation efficiencies of 0.6 and 1.1% for the two varieties although the transformation efficiency can be much higher in individual experiments (up to 3.8%, data not shown). Different segregation patterns were often observed among the progeny of the multiple shoots derived from a given SLS (Supplementary Table 1), suggesting that multiple independent transgenic plants can be regenerated from a single explant. TAIL-PCR was performed on 65 T1 lines derived from 31 SLS to determine whether multiple lines from a single SLS correspond to clonal or independent transgenic events. The TAIL-PCRs were not successful for every set of SLS, but we were able to identify five SLS in which the corresponding lines with more than one TAIL PCR fragment. An example is shown in Supplementary Fig. 2. Together, the data suggest that the actual transformation efficiency is higher than calculated above.

Stable *35S::BnBBM:GR* transformants are highly regenerative

Two single locus, homozygous *35S::BnBBM:GR* lines were selected for further phenotypic analysis. Seeds were sown on either MS20, MS20 supplemented with either DEX or TDZ or MS20 supplemented with both DEX and TDZ. Seedlings of the two *35S::BnBBM:GR* lines were indistinguishable from the wild type when grown on MS20 (Fig. 2a). *35S::BnBBM:GR* seedlings grown on DEX-containing medium were severely delayed in their initial growth as compared to wild-type plants growing on the same medium. Seedlings from one of the two lines germinated, but failed to develop further. Seedlings of both

Fig. 2 Regeneration response of stable *35S::BBM:GR* sweet pepper lines. **a–d** 24-day-old seedlings germinated on medium with the indicated supplements; **e–h** feather-cut cotyledons of 10-day-old seedlings incubated for 14 days on medium with the indicated supplements. Shoot-like structures are indicated by an arrow; **i–l** feather-cut leaves of 4-week-old plants incubated for 14 days on medium with the indicated supplements; **m** *35S::BBM:GR* somatic embryos; **n** immature wild-type zygotic embryo; **o** somatic embryo formation on wild-type zygotic embryos. *MS20* Murashige and Skoog medium with 2% (w/v) sucrose, *TDZ* thidiazuron, *DEX* dexamethasone

lines showed a thickened root, a pronounced apical hook (Fig. 2b) and were agravitropic. The cotyledons that remained in contact with the medium eventually swelled and formed irregular protruberances lacking a defined structure. Wild-type and *35S::BnBBM:GR* seedlings plated on TDZ-containing medium developed as on the control MS20 medium (Fig. 2c). Wild-type and *35S::BnBBM:GR*

seedlings growing on medium supplemented with both DEX and TDZ showed a combination of the phenotypes observed in the presence of the individual compounds (Fig. 2d). In addition, cotyledons of *35S::BnBBM:GR* seedlings that remained in contact with the medium eventually developed into a callus mass and produced a few SEs (data not shown).

The ability of *35S::BnBBM:GR* explants to form SEs prompted us to assess the regenerative capacity of different organs. Segments of roots and hypocotyls and feather-cut cotyledons from 10-day-old seedlings, and feather-cut leaves from 4-week-old homozygous *35S::BnBBM:GR* plants were placed onto MS20 or MS20 supplemented with TDZ, DEX or both TDZ and DEX. Root and hypocotyls segments formed callus but did not regenerate under any of the conditions tested (data not shown). Cotyledons and leaves cultured on MS20 formed white callus at the wounded edges of the explant (Fig. 2e, i). TDZ stimulated white callus production in cotyledons and leaves, and also induced SLS formation at the wounded edges of cotyledons (Fig. 2g, k). Culturing cotyledons and leaves on medium with DEX (Fig. 2f, j) or DEX and TDZ (Fig. 2h, l) induced prolific SE formation. SE induction was greatly diminished when uncut leaves and cotyledons were used as explants (data not shown). Quantitative differences in SE production were not observed when TDZ was replaced by the cytokinins benzylaminopurine and zeatin riboside (data not shown). SE induction was mainly observed on the surface of the explant adjacent to the cut edge, and SEs appeared to develop directly from the underlying tissue, rather than indirectly through an intermediate callus phase. SEs formed on DEX-containing medium generally developed to the globular stage (Fig. 2f, j), while SEs growing on medium containing TDZ (or other cytokinins) and DEX progressed further to the heart-shaped stage and beyond, in which the cotyledons are visible (Fig. 2h, l). SEs from *35S::BBM:GR* explants induced on TDZ (or other cytokinins) and DEX have a clear bipolar structure (Fig. 2m), and are more similar to wild-type zygotic embryos (Fig. 2n) than to standard SEs derived from immature wild-type zygotic embryos (Fig. 2o). *35S::BBM:GR* SEs could be converted into plantlets by plating them on RM. While individual cytokinins did not affect SE production quantitatively, they did influence the ability of SEs to convert into plantlets. The highest conversion rate (50%) was obtained with embryos that were induced in the presence of benzylaminopurine (Supplementary Table 2).

Discussion

Pepper is a major crop that is grown world-wide and whose production is threatened by various biotic and abiotic stresses. Resistances can often be found in wild relatives, but there are often strong breeding incompatibilities between *Capsicum* species that are not easy to circumvent (Jae et al. 2006; Onus and Pickersgill 2004). Traits from incompatible wild relatives could be introduced into

cultivated peppers via genetic transformation; however, peppers, especially the sweet genotypes, are highly recalcitrant for transformation.

Here, we describe a reliable and efficient transformation protocol for sweet pepper genotypes that takes advantage of the enhanced regeneration response conferred by the BBM AP2/ERF transcription factor. The protocol is straightforward in that additional measures such as grafting SLS onto a rootstock (Mihálka et al. 2003), a long phase of shoot elongation (“normalization”) (Engler et al. 1993) or the addition of auxin to enhance rooting (Engler et al. 1993; Khan et al. 2006) were not required. Direct comparison of our sweet pepper transformation efficiencies with published protocols is difficult as in practice there are no routine, reliable and reproducible protocols that are applicable to more than one genotype. The comparison is further complicated by the lack of information on the transformation efficiency (Harpster et al. 2002; Zhu et al. 1996) or the heritability of the transgene (Dabauza and Pena 2003; Engler et al. 1993; Manoharan et al. 1998; Mihálka et al. 2003; Shivegowda et al. 2002). Our transformation efficiencies of 0.6 and 1% obtained with two recalcitrant sweet pepper genotypes are higher on average than the 0.03–0.6% reported for the most responsive *C. annuum* chili pepper genotypes (Ko et al. 2007; Lee et al. 2004; Manoharan et al. 1998).

This and previous studies (Wolf et al. 2001) suggest that the few regenerating structures that are obtained in standard pepper transformation protocols are not susceptible for agrobacterium-mediated transformation. The mechanism by which the BBM protein closes the gap in competencies for transformation and regeneration in pepper is not clear. BBM might exert a positive effect on the transformation efficiency by creating a cellular environment that is both susceptible to transformation and regeneration, or by increasing the total number of regenerating cells (SLS), thereby increasing the probability that both processes coincide in one cell. *35S::BBM:GR* explants not only produce a higher number of SLS than control explants; they also elongate to produce shoots at a higher frequency. Again, the underlying mechanism is not clear. Both *35S::GUS* and *35S::BBM:GR* explants initially produce morphologically similar SLS that grow in dense rosettes with no clear boundaries between them, suggesting a non-functional or missing SAM. Somewhere during the regeneration of BBM-SLS, a functional SAM and vascular bundles are formed that allow the shoots to elongate and develop into a normal plant. The ability of BBM to induce direct regeneration, i.e., without an intervening callus phase, may promote improved shoot polarity and differentiation.

Efficient in vitro regeneration systems based on somatic embryogenesis can facilitate the classical breeding process by providing large amounts of clonal material for

propagation, as well as explants for transformation. SE production from immature zygotic embryos on solid medium has been reported in *C. annuum* (chili and sweet pepper types) and *C. chinense* although the induction frequencies are low (maximum 8 SE/explant) (Binzel et al. 1996; Harini and Lakshmi Sita 1993; Steinitz et al. 2003), and the SEs can exhibit a high frequency of morphological defects that affects their conversion into seedlings (Steinitz et al. 2003). Solís-Ramos et al. (2009) used inducible expression of the arabidopsis WUSCHEL (WUS) homeobox transcription factor (Zuo et al. 2002) to enhance SE formation in *C. chinense* L. A small number of globular structures could be induced to form on primary stem explants transformed with the inducible WUS construct but the embryos failed to develop further and eventually died. In contrast, stable *35S::BBM:GR* transgenics exhibited an extremely high regeneration capacity, producing hundreds to thousands of well-formed embryos per explant that could be converted at a high frequency into seedlings.

A number of strategies can be used to implement a BBM-based transformation technology. For example, a second gene of interest can be co-transformed along with the *35S::BBM:GR* construct or stable, highly regenerative *35S::BBM:GR* transformants could be used as explants for the introduction of a second gene of interest. In both examples, the positive effect of the BBM protein on the regeneration process can serve as a selectable marker during (co-)transformation of a second gene of interest, which can itself be selected in the classical way (e.g., using antibiotic- or herbicide resistance) or via PCR. For some purposes it may be desirable to avoid stable integration of the *35S::BBM:GR* transgene. This could be circumvented by transient expression techniques (Vergunst et al. 2000) or by segregation of the *35S::BBM:GR* transgene in progeny lines.

The sweet pepper transformation system described here opens up possibilities for the introduction of new disease and abiotic stress resistances, as well as for important reproductive and architecture traits. In addition to these practical applications, this transformation system provides opportunities for building up fundamental research tools that can be used to understand gene function in *Capsicum* spp.
